### Summary

**Objectives:** It's known that during cultivation, adherent cells of umbilical cord blood (UCB) form a monolayer reminiscent, in its composition, of the stromal monolayer of bone marrow (BM) culture. However, the presence of mesenchymal stem cells (MSCs) in UCB still remains uncertain. This study was performed to investigate the composition and some functional characteristics of MSC-like cell populations revealed in the cord blood monolayer culture.

**Materials and methods:** Forty-three human UCB samples were under study. All the samples were obtained during full-term deliveries. To produce monolayer cultures, mononuclear cell fractions from UCB were cultivated in a culture medium containing DMEM with 20% FCS, supplied with 1% Pen/Strep. Phenotypic patterns of UCB culture were assessed with a panel of monoclonal antibodies specific for CD34; CD117; CD45; CD14; CD3; CD19; CD31; CD90; HLA DR; and HLA ABC. To determine the functional characteristics of MSCs derived from UCB culture, their differentiation ability and stimulation of hematopoietic colony formation activity were evaluated.

**Results:** In most cases, the cultures of plastic-adherent cells proved to be heterogeneous. Both spindle-shaped and polygonal cells were observed. In some samples, clonal growth could be detected. However, the number of fibroblastoid cells did not increase 100 cells per colony. Large colonies were registered in three UCB samples of the 43 under study. As evidenced by immune phenotyping, the monolayer UCB cultures were rather polymorphic and dissimilar in each sample. Most of the cells present in the cultures were macrophages (CD45<sup>+</sup>). However, we also found different amounts of presumably mesenchymal cells, including cells with an endothelial phenotype (CD34<sup>+</sup>CD31<sup>+</sup>).

Specific staining showed that the cells from a UCB monolayer culture have the capacity to differentiate into adipocytes and osteoblasts. In some cultures, however, induction of differentiation lead to the detachment of a major cell fraction. Hemostimulatory ability of UCB monolayer cultures depended on the phenotype composition of the monolayer culture. CD45<sup>+</sup> and CD14<sup>+</sup> cells, evidently, are stimulatory for granulocyte-macrophage colony formation. Moreover, levels of non-hematopoietic subpopulations (CD90<sup>+</sup>CD31<sup>-</sup>) in UCB cultures showed a direct correlation with the numbers of CFU-GM colonies produced.

**Conclusion:** UCB contains a subpopulation of non-hematopoietic cells possessing phenotypic and some functional characteristics of bone marrow derived mesenchymal stem cells. However, the low content and variable numbers of such cells provide some doubts on the viability of UCB as an alternative source for MSC.

**Keywords:** umbilical cord blood, mesenchymal stem cells (MSC), immunophenotyping, cell culture

### Introduction

Mesenchymal stem cells (MSC) constitute a rare population of multipotent progenitors capable of both supporting hematopoiesis and differentiating into at least osteogenic, adipogenic and chondrogenic lineages [1-3]. Moreover, they exhibit immunomodulatory activity, induce immunotolerance in case of allogeneic

transplantation [4], and possess the ability to expand in relatively simple in vitro systems [5-7]. These characteristics make MSCs very promising candidates in the development of new cell-based therapeutic strategies, such as the treatment of tissue injuries or the supportive application by hematopoietic stem cell transplantation.

Taking into consideration that the number of MSCs and their differentiation capacity decline with age [8], most relevant is the search for alternative sources of these cells.

The advantages of umbilical cord blood (UCB), as a source of stem cells, include their accessibility, non-invasive sampling and, thus, their safety for potential donors [9-11]. Another reason for this study was due to some controversial data about amounts of mesenchymal precursors in UCB [12-17]. Mesenchymal precursors (CFU-F) are found in foetal blood in the early gestational period at concentrations equal to their amounts in the bone-marrow of newborns [18]. However, after the second trimester, the number of MSCs decreases considerably, and, at birth, their frequency in UCB is quite accidental [12,19]. The need for testing of some standards for culturing adhesive cell fractions from UCB, as well as assessment of their contents and functional characteristics provided other motivations for this study.

## Materials & Methods:

### Collection of UCB

UCB samples (mean volume of 60 ml) from full-term deliveries were collected from the unborn placenta after obtaining the mothers' informed consent. A sterile bag system containing citrate phosphate dextrose (CPD) anticoagulant within the collection bag (manufactured by Terumo, Japan) was used. The units were stored at room temperature before processing (up to 33 hours).

### Isolation and Culture of Adherent Cells from UCB

To isolate mononuclear cells (MNCs), each UCB unit was diluted 1:1 with phosphate-buffered saline (PBS)/2 mM EDTA (Biolot, Russia), and carefully loaded onto Ficoll-Hypaque solution (Lympho separation medium, ICN, USA,  $d=1.077$ ). Following a density gradient centrifugation at 435 g for 30 minutes at room temperature, MNCs were removed from the interphase layer and washed two to three times with PBS/EDTA. UCB-derived MNCs were set at a density of  $1 \times 10^6/\text{cm}^2$  into six-well culture plates (Corning, USA) containing DMEM low-glucose medium (Gibco, USA) with 20% fetal calf serum (FCS) from selected lots, penicillin 100 UI/ml, and streptomycin 0.1 mg/ml (Gibco, USA). After overnight incubation at 37°C in a humidified atmosphere containing 5% carbon dioxide, nonadherent cells were removed and fresh medium was added to the wells. Cell cultures were maintained, and remaining nonadherent cells were discarded via the complete exchange of culture medium every 7 days. Culture plates were screened continuously to detect developing colonies of adherent cells. The number of fibroblast colony forming units (CFU-F) was calculated by counting the number of colonies per  $10^8$  MNCs.

Fibroblast-like cells were detached between days 16 through 20 after initial plating using 0.04% Trypsin/0.03% EDTA (Gibco, USA). The recovered cells were replated at a density of 4,000 to 5,000 cells/cm<sup>2</sup>.

### Collection and Isolation of Control MSCs from Bone Marrow

MSCs from bone marrow (BM) were obtained by bone marrow puncture. BM cells were aspirated into a 5-ml syringe containing

CPD anticoagulant. A total of six samples were obtained, with the donor age ranging from 24 to 56 years. To isolate MSCs from BM, the aspirate was diluted 1:5 and processed as described above. In contrast to MNCs from UCB samples, BM-derived MNCs were cultured at a density of  $1 \times 10^6$  cells/cm<sup>2</sup> in T75 culture flasks (Corning, USA), and the first change of medium was performed 3 days after initial plating. Two weeks later, at reaching 80%–90% confluence, MSCs were detached using trypsin and replated as described for the UCB-derived adherent cells.

### Primary Fibroblasts as Controls

Primary cultures of normal human dermal fibroblasts served as negative control in differentiation and comparative gene expression studies. Culture conditions were comparable to BM MSC's expansion: DMEM low glucose medium (Gibco, USA) containing 20% fetal calf serum (FCS), penicillin 100 UI/ml, and streptomycin 0.1 mg/ml (Gibco, USA).

### Immune Phenotypic Analysis

To analyze the cell-surface expression of typical marker proteins in UCB- and BM-derived adherent cells, each from primary culture and second passage, these were labeled with the following anti-human antibodies: CD34 PE; CD34 FITC, CD45 FITC; CD45 PE; CD14 FITC; CD31 PE; CD31 FITC; CD61 FITC; CD3 FITC; CD19 PE; CD117 PE; HLA ABC FITC; HLA DR, DP, DQ FITC; CD 90 PE (Becton Dickinson, USA). Murine isotype antibodies (Becton Dickinson, USA) served as respective controls. Ten thousand labeled cell aliquotes were analyzed using a FACScan flow cytometer running CellQuest software (Becton Dickinson, USA).

Aiming at a subset analysis of the population, we employed the following indices:

- hematopoietic cells index – CD45<sup>+</sup> to CD45<sup>-</sup> cells
- myeloid cell maturation index – CD14<sup>+</sup> to CD45<sup>+</sup> cells
- hematopoietic progenitor cell index – CD34<sup>+</sup>CD45<sup>+</sup> to CD45<sup>+</sup> cells
- endothelial cell-precursors index – CD34<sup>+</sup>CD45<sup>-</sup> to CD45<sup>-</sup> cells
- mesenchymal precursors index – CD90<sup>+</sup>CD31<sup>-</sup> to CD45<sup>-</sup> cells

### In vitro Osteogenic and Adipogenic Differentiation Studies

To induce osteogenic differentiation, the cells were seeded at a density of  $3.1 \times 10^3$  cells/cm<sup>2</sup> and cultured in six-well microplates (Costar, USA), until they reached approximately 80% confluence. Additional culture was performed in osteogenic differentiation medium supplemented with 0.1 μM dexamethasone, 10 mM β-glycerophosphate, 0.05 mM ascorbate, and 10% FCS. The onset of osteoblast formation was evaluated after 3 weeks via calcium accumulation. Accumulation of mineralized calcium phosphate was assessed with von Kossa staining after the protocol from Cheng et al. [20], with a few modifications. The cells were fixed for 15 minutes in 10% formalin (Sigma-Aldrich), and, after washing, they were incubated with 5% silver nitrate (Sigma-Aldrich) for 15 to 30 minutes. Pyrogallol 1% (Merck, Canada) and sodium thiosulfate 5% (Sigma-Aldrich) were used to develop and register a resulting image. In addition, the mineralized matrix was also evaluated by Alizarin-red S staining using 4% formaldehyde for fixation and 1% aqueous Alizarin-Red S (Sigma-Aldrich) solution.

Adipogenic differentiation was induced according to the protocol of Pittenger et al. [2]. Special induction medium, containing DMEM (high glucose), 1  $\mu$ M dexamethasone, 0.5 mM 3-isobutyl-1-methyl-xanthine, 10  $\mu$ g/ml recombinant human (rh) insulin, 0.2 mM indomethacin, and 20% FCS, was added for 2 to 3 days to the culture microplates. It was then replaced by maintenance medium containing only rh-insulin and 20% FCS. Induction of adipogenic differentiation was apparent via the intracellular accumulation of lipid-rich vacuoles that stained with Oil Red O (Sigma-Aldrich). The cells were fixed with 10% formalin, washed, and stained with a working solution of 0.18% Oil Red O for 5 minutes.

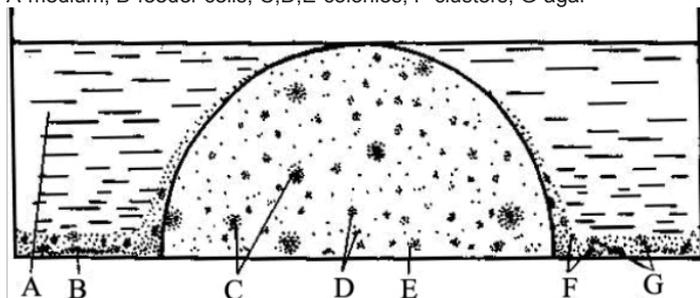

### In vitro Model for Studying Colony-stimulating Activity of UCB cells

An essential property of mesenchymal stem cells is their capacity to support hematopoiesis. In order to assess the hemostimulating capacity of the UCB monolayer culture, a modified technique proposed by Afanasyev [21,22] was used (Figure 1). This method determines the clonogenic capacity of granulocytic-macrophage colony forming units (CFU-GM) in “agar drop-liquid medium” culture.

The monolayer culture of UCB-derived adherent cells (confluence

rate: 70–80%) was used as a source of colony-stimulating activity of MSC from UCB. The cells (CFU-GM) from the UCB mononuclear fraction were targeted in this assay, providing clonal growth in agar cultures. Semisolid agar drops containing target cells were prepared on dry surfaces of sterile Petri dishes. The resulting semisolid drops were transferred to the dishes, and co-incubated for 7 days in the following four versions: 1) with complete culture medium only; 2) with medium containing standard-type leukocyte feeder; 3) with UCB confluent monolayer culture; 4) with both UCB confluent monolayer culture and standard-type leukocyte feeder. Each experiment was performed at least twice.

Colony-forming ability (CFA) and cluster-forming ability (CIFA) were classified according to the number of cells in the colonies (small colonies: containing 20–40 cells; medium-size colonies: 41–100 cells; and large colonies: more than 100 cells) and clusters (large clusters: 10–19 cells; small clusters: 5–9 cells). Depending on the total number of colonies and clusters, the cloning efficiency (CE) per  $1 \times 10^5$  explanted mononuclear cells was assessed. A “colony-to-cluster” ratio (Co-Cl) and percentage of large colonies (LC) were supplemental parameters assessed in these cell cultures. Using such parameters, the proliferative potential of the target progenitor cells was tested.

### Total RNA Isolation and RT-PCR

Total RNA was extracted from 3 to  $30 \times 10^5$  MSCs using Trizol Reagents (Invitrogen, USA), according to the manufacturer's instructions. mRNA was subject to reverse transcription (RT) using Superscript II Kit (Invitrogen, USA), again using the manufacturer's instructions. The resulting cDNA was amplified using an ABI GeneAmp PCR System 2400 (Perkin Elmer Applied Biosystems, Boston, MA) at 94°C for 40 seconds, 56°C for 50 seconds, and 72°C for 60 seconds for 35 cycles, after initial denaturation at 94°C for 5 minutes. Primers used for PCR are listed in Table 1. Fifteen microliters of PCR reaction were fractionated by agarose gel electrophoresis.

## Statistical Analysis

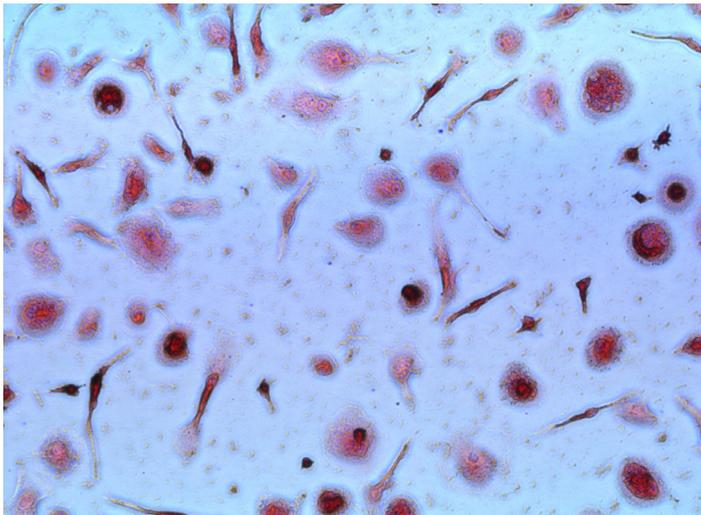

The statistical significance of the inter-group differences was evaluated with the Mann-Whitney test. The degrees of correlations between the parameters were evaluated by the Spearman test. The differences were considered significant by p values <0.05. The Statistica 6.0 software package was used for all statistical analyses.

## Results & Discussion:

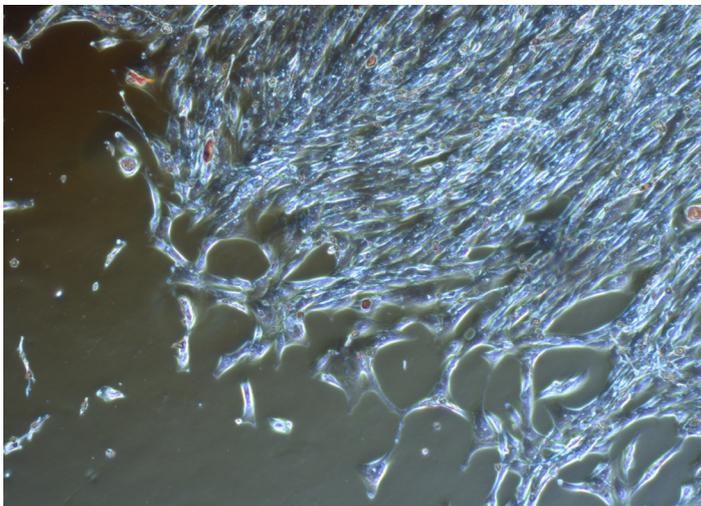

In most cases, the cultures of plastic-adherent cells proved to be heterogenous. Two main morphological cell types were discernible: spindle-shaped cells that are presumably regarded as mesenchymal stem cells (MSC), and polygonal cells that are most likely of hematopoietic origin (**Figure 2**).

In some UCB samples, clonal growth was observed, however the mean cell number per colony did not increase over 100 cells (**Figure 3**). Large colonies were detectable in 3 of the 40 UCB samples under study. These colonies (>1000 cells per colony) consisted of closely packed, spindle-shaped cells, typical of fibroblast morphology cells.

**Figure 2. Heterogeneous UCB culture.** No colony formation was observed. UCB samples produced a minimal, non-confluent adherent layer of heterogeneous cells.

**Figure 3. CFU-F in UCB culture.** Adherently growing cells of fibroblastic morphology formed big colonies in 3 UCB samples.

**Table 2. The composition of the UCB monolayer culture**

## The Phenotypic Composition of UCB Monolayer Cultures

Our efforts to define a distinct phenotype characteristic for MSC have been confounded by the fact that these cells can express a range of cell lineage-specific antigens [2,23].

During analysis of the predominant cellular types, it was discovered that the major fraction (median 60.17%) of plastic-adherent cells from UCB were of hematopoietic origin (CD45<sup>+</sup>) (**Table 2**). One-third of the CD45-positive cells belonged to the CD14-positive population fraction (median 14.81%). Cells in the monolayer with an osteoclast-like phenotype (CD45<sup>+</sup>CD61<sup>+</sup>) constituted approximately 1.5%. The cells phenotypically comparable with hematopoietic stem cells (HSC-like cells: CD34<sup>+</sup>CD45<sup>-</sup>, CD34<sup>+</sup>HLA DR<sup>-</sup>, CD117<sup>+</sup>) were present at a low concentration in the UCB monolayer culture—less than 1.5%.

The numbers of endothelial-like cells in the monolayer cultures were comparable to HSC-like cells. With this background, a heterogenous population of CD45<sup>-</sup>CD31<sup>+</sup> phenotype was the most prominent one. Despite a lack of specific markers that could characterize a population of MSC's, we attempted to determine the quantity of these cells in the culture, based upon the fact that mesenchymal stem cells of the bone marrow do not express common leucocytic antigen CD45 and HLA class II antigens but do express class I HLA antigens and the CD90 marker. In this connection, we studied the following populations of phenotypically MSC-like cells: CD45<sup>-</sup>HLA ABC<sup>+</sup> and CD90<sup>+</sup>CD31<sup>-</sup>.

Aiming for further validation of available cultural conditions for expansion of MSCs and endothelial precursors, we assessed the following factors influencing the terms of cultivation period in a primary culture under the conditions of initial culture and subsequent passages. During long term cultures (**Table 3**), the index of cells with hematopoietic markers decreased progressively, and the index of myeloid cell maturation decreased as well, providing evidence of the elimination of hematopoietic cells during the cultivation. We have revealed that the index of HSC-like cells

**Table 3. Influence of cultivation period on composition of primary UCB culture**

Indices of structural analysis:	Cultivation period (primary culture)		Differences significance (Mann-Whitney test)
	less than 23 days	more than 23 days	
	median 25-75 %	median 25-75 %	
CD45 <sup>+</sup> to CD45 <sup>-</sup>	1,511 0,688-2,819	0,314 0,153-0,629	0,001
CD45 <sup>+</sup> CD14 <sup>+</sup> to CD45 <sup>+</sup>	0,251 0,109-0,495	0,159 0,096-0,357	>0,05
CD34 <sup>+</sup> HLA-DR <sup>-</sup> to CD34 <sup>+</sup>	37,33 19,99-55,45	81,98 43,64-95,12	0,001
CD34 <sup>+</sup> CD45 <sup>+</sup> to CD45 <sup>+</sup>	0,008 0,005-0,018	0,051 0,023-0,146	0,002
CD117 <sup>+</sup> to CD45 <sup>+</sup>	0,010 0,006-0,017	0,086 0,030-0,143	0,002
CD34 <sup>+</sup> CD45 <sup>-</sup> to CD45 <sup>-</sup>	0,013 0,005-0,017	0,025 0,016-0,078	0,02
CD45 <sup>+</sup> HLA1 <sup>+</sup> to CD45 <sup>-</sup>	0,066 0,026-0,080	0,060 0,027-0,105	>0,05

(hematopoietic progenitor cell index) increases during prolonged cultivation, i.e. an index, reflecting a ratio of cells, phenotypically similar to hematopoietic stem cells, to the total number of CD45<sup>+</sup>-cells (CD34<sup>+</sup>CD45<sup>+</sup>, CD117<sup>+</sup>). This fact implies that this population is eliminated slower than other hematopoietic cells recovered in the UCB monolayer culture.

Moreover, the percentage of CD34<sup>+</sup>HLA DR<sup>-</sup> cells increases (37.33 to 81.98, p=0.001) in relation to general CD34<sup>+</sup>-positive population, thus supposing that these cells undergo selective proliferation under the given cultural conditions. This result could indirectly confirm a theory that this population is presented via stromal component [24,25]. In the course of long-term cultivation, the index of endothelial cells is shown to be increased (0.013 to 0.025, p=0.02). This fact proves these cultural conditions are favorable for endothelial precursors' maintenance. When assessing the fractions that include mesenchymal precursors, we have found a tendency for an increase in the relative amounts of the CD45<sup>+</sup>HLA ABC<sup>+</sup> subpopulation. However, when analyzing these populations with regard of all non-hematopoietic cells,

**Table 4. Influence of culture passage on the structure of primary UCB culture**

Indices of structural analysis:	Primary UCB culture	1 <sup>st</sup> passage	Differences significance (Wilcoxon signed-rank test)
	median 25-75 %	median 25-75 %	
CD45 <sup>+</sup> to CD45 <sup>-</sup>	3,198 1,526-3,511	1,608 0,372-1,999	<0,016
CD34 <sup>+</sup> CD45 <sup>+</sup> to CD45 <sup>+</sup>	0,003 0,002-0,005	0,013 0,006-0,025	<0,032
CD3 <sup>+</sup> to CD45 <sup>+</sup>	0,003 0,002-0,007	0,013 0,008-0,022	<0,062
CD31 <sup>+</sup> CD34 <sup>+</sup> to CD45 <sup>+</sup>	0,013 0,004-0,021	0,028 0,007-0,064	<0,06
CD45 <sup>+</sup> HLA1 <sup>+</sup> to CD45 <sup>-</sup>	0,081 0,050-0,132	0,021 0,015-0,026	<0,046

we did not observe such a tendency. This fact may reflect the persistence of a steady phenotype of these cell populations upon durable cultivation.

During the process of culture passage, we could reveal a decrease of the hematopoietic cell index (3.19 to 1.6, p<0.016) (Table 4). This data may show the inability of the majority of hematopoietic cells for repeated adhesion, thus resulting in their elimination from the monolayer culture. At the same time, the cells phenotypically similar to HSC-like cells (CD34<sup>+</sup>CD45<sup>+</sup>) and lymphocytes (CD3<sup>+</sup>), were still able to adhere recurrently, when compared with other hematopoietic cells. Among cell populations containing mesenchymal precursors, it was noticed that the cells expressed class I HLA antigens, possessed a reduced adhesive ability, and were subject to elimination with sequential passing.

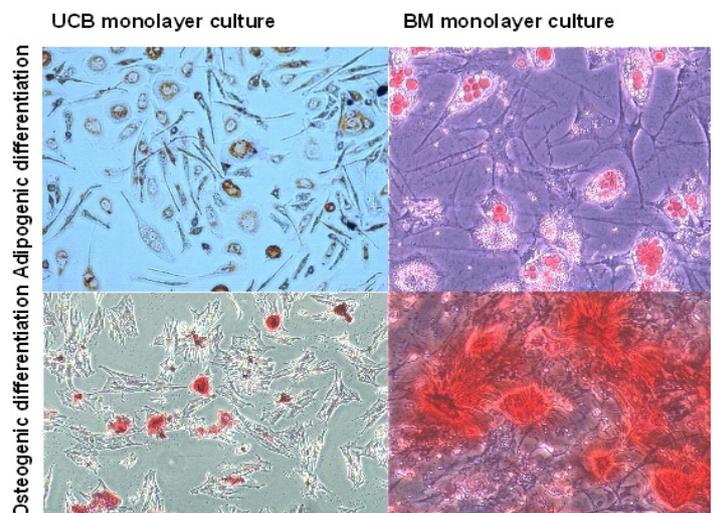

When comparing the phenotypical composition of mononuclear fraction and monolayer culture from UCB (Table 5) we discovered that the percentage of cells with CD34<sup>+</sup>CD45<sup>+</sup> phenotype in the culture decreased considerably, along with an increased percentage of cells with CD34<sup>+</sup>HLA DR<sup>-</sup> phenotype. Therefore, we can suggest that these cultural conditions may be applied for isolation of the given cell type.

This may be also proven by the data from semi-solid methylcellulose culture. The cells from monolayer cultures under study were incapable of forming hematopoietic colonies in the presence of standard hematopoietic growth factors (SCF, GM-CSF, IL-3, IL-6, G-CSF, EPO). This may result from a deficiency of clonogenic precursors in the monolayer, as well as an absence of clonogenic potential among hematopoietic stem-like cells.

The fraction of endothelial cells was higher in the monolayer culture. The percentage of hematopoietic-stem-like-cells and endothelial precursors decreased considerably during the initiation of the culture (38.87 to 1.34, p<0,02).

Analogous to Bieback's paper [12], when assessing the time parameters of sampling and storage of umbilical blood specimens we have revealed a tendency towards a decreased concentration

**Figure 4. Differentiation assay of BM and UCB monolayer culture.** Formation of mineralized matrix by Alizarin Red and von Kossa staining evidenced osteogenic differentiation. Adipogenic differentiation was evidenced by the formation of lipid vacuoles in phase-contrast photograph and by oil-red O staining.

**Table 5. The phenotypic composition of the mononuclear fraction and monolayer culture of UCB**

of mesenchymal like stem-cells in the monolayer culture, when a prolonged time-period prior to processing umbilical blood sample with subsequent cultivation occurs (data not shown).

#### ***In vitro* differentiation of UCB-derived MSC-like cells into adipocytes and osteocytes**

Taking the lack of specific markers for identification of mesenchymal precursors into consideration, we tried to reveal the functional characteristics of the given types of cells and to assess the differential potentials in the framework of orthodox plasticity. It is shown that the cells of the UCB monolayer culture are capable of dividing and differentiating to adipocytes and osteoblasts, as was proven by their specific staining (**Figure 4**). In this figure (upper picture), red lipid inclusions are readily seen in differentiated adipocytes. In the lower picture, calcium insertions in the osteocytes are stainable red or black. In some cultures, however, induction of differentiation initiated detachment of most cells from plastic surface. As a result, the present conditions for differentiation of mesenchymal stem cells from BM are not quite appropriate for induced differentiation of UCB-derived mesenchymal precursors.

#### **Ability of UCB monolayer culture to support *ex vivo* expansion of CFU-GM**

Concerning efficiency of CFU-GM cloning, the UCB monolayer culture does not differ from standard leucocytic feeder. However, when using umbilical cord blood culture as a feeder, UCB-generated growth-promoting capacity and percentage of large colonies were higher (data not shown). Additional analysis (**Table 6**) leads us to suggest that hematopoietic cells from a UCB monolayer culture have certain advantage over non-hematopoietic cells in terms of colony-stimulation activity ( $r=0.71$ ,  $p=0.035$ ), at least in this *in vitro* model. With respect to non-hematopoietic cells, growth

**Table 6. Hemostimulating capacity of UCB-culture**

Phenotype relation	Correlation index/significance	GM-CFU proliferation index		
		CE	CO-CL	BC
CD45 <sup>+</sup> to CD45 <sup>-</sup>	r=	0,6667	0,3833	0,7029
	p=	0,0499	0,3085	0,0347
CD90 <sup>+</sup> CD31 <sup>-</sup> to CD45 <sup>-</sup>	r=	0,6500	0,3500	0,8201
	p=	0,0581	0,3558	0,0068
CD14 <sup>+</sup> to CD45 <sup>+</sup>	r=	0,5333	0,2500	0,6695
	p=	0,1392	0,5165	0,0486

of cellular elements bearing MSC-markers (CD90<sup>+</sup>CD31<sup>-</sup>) was accompanied by significant increase in CFU-GM proliferative activity ( $r=0.82$ ,  $p=0.007$ ). Higher percentages of monocytes/macrophages, as among hematopoietic elements, is accompanied by growing numbers of large colonies ( $r=0.67$ ,  $p=0.045$ ), without producing any significant impact upon cloning efficiency of the progenitors.

Some references in the literature contain similar data obtained with another model, i.e., target cells were incubated with UCB cells in suspension cultures, followed by methyl cellulose cultures of non-attached cell populations in presence of standard growth factors, such as SCF, GM-CSF, G-CSF, IL3, IL6 and EPO [26,27]. Within our model, only umbilical cord blood cells of a monolayer culture were used as the colony stimulation source.

#### **Comparative gene expression studies**

When assessing the expression of some genes, we have found that the mRNA profile of bone marrow culture did not differ from the cells of UCB culture. Thrombopoietin was an exception, since specific mRNA was not detectable in the 1<sup>st</sup> passage culture of UCB cells (**Table 7**).

**Table 7. mRNA profile of MSC-like cells from different sources**

Gene	BM-derived MSC	human skin fibroblasts	UCB-derived MSC
Cadherin 11 (CDH11)	-	-	-
CD 106 (VCAM1)	+	+	+
CD 29 (ITGB1)	+	+	+

Tropomyosin 1 alpha (TPM1)	+	+	+

## Conclusions

- Increased cultivation time of UCB mononuclear fraction (over 23 days) leads to a gradual elimination of hematopoietic cells from the culture and an increase in mesenchymal stem cells and endothelial progenitor cells.
- Cellular phenotype in the culture changes during passages, i.e., the quantity of hematopoietic cells is considerably decreased. This results in increased concentration of non-hematopoietic components of the umbilical blood monolayer culture during serial passaging.
- An increased time period of UCB sampling is associated with a decrease in the relative quantity of mesenchymal-like stem cells, along with an increase in the concentration of endothelial precursors in the culture.
- Mesenchymal stem-like cells of UCB have the capacity to differentiate into adipogenic and osteogenic lineages, thus suggesting their functional consistency.
- The adhesive fraction of the primary monolayer culture exerts a stimulatory effect upon the colony formation of GM precursors, being similar in type and degree of influence to a standard peripheral blood feeder. The primary effect upon their proliferative capacity may be produced by cellular elements with MSC (CD90<sup>+</sup>CD31<sup>-</sup>) markers.
- An increased time interval during sampling and storage of UCB leads to a decrease in the hemostimulating capacity.
- The variable contents of MSC-like cells and CFU-F in umbilical cord blood and/or their reduced repopulation ability may limit their application as an alternative source of MSCs.

## Состав и функциональные особенности монослойной культуры пуповинной крови человека

Бархатов И.М., Румянцев С.А., Владимирская Е.Б., Афанасьев Б.В.

### Резюме

**Введение:** РВ условиях монослойной культуры клетки пуповинной крови способны прикрепляться к пластику и по своей морфологии напоминают культивируемые в сходных условиях мезенхимальные стволовые клетки (МСК) костного мозга. Однако присутствие в прилипающей фракции пуповинной крови МСК до сих пор не является очевидным. Данное исследование выполнено с целью определения состава и ряда функциональных свойств МСК-подобных клеток в монослойной культуре пуповинной крови (МКПК) человека.

**Материалы и методы:** Исследовали сорок три образца пуповинной крови, полученные в срочных родах на фоне неосложненной беременности у рожениц при атравматичном заборе. Исследования проводили после 19-31 часов хранения образца. Ядродержащие клетки выделяли на градиенте плотности фикола (1,077 г/мл), затем помещали в полную культуральную среду, содержащую среду DMEM LG, эмбриональную телячью сыворотку - 30%, пенициллин (100 Ед/мл), стрептомицин (0,1 мг/мл). Анализ фенотипа монослойной культуры ПК и ее мононуклеарной фракции проводили на проточном цитофлюориметре FACScan. Были использованы следующие конъюгированные флуорохромами антитела: CD34 PE; CD34 FITC, CD45 FITC; CD45 PE; CD14 FITC; CD31 PE; CD31 FITC; CD61 FITC; CD3 FITC; CD19 PE; CD117 PE; HLA ABC FITC; HLA DR. С целью определения гемостимулирующих свойств монослойной культуры ПК проводили клонирование гранулоцитарно-макрофагальных предшественников (КОЕ-ГМ) в культуральной системе «агаровая капля-жидкая среда». В качестве источника колониестимулирующей активности ПК использовали МКПК. Клетками-мишенями были КОЕ-ГМ мононуклеарной фракции ПК, дающие клональный рост в агаровой культуре. Для индукции дифференцировки МСК-подобных клеток ПК в адипогенном и остеогенном направлении клетки помещали в полную среду с добавлением дексаметазона ( $1 \times 10^{-7}$  М); инсулина ( $1 \times 10^{-9}$  М) или  $\beta$ -глицерофосфата ( $7 \times 10^{-3}$  М); дексаметазона ( $1 \times 10^{-8}$  М); аскорбиновой кислоты ( $2 \times 10^{-4}$  М) соответственно. Оценка экспрессии генов (CDH11, VCAM1, ITGB1, IL6ST, TFRC, ALCAM, MPL, TPO, ENG, NT5E, IL6R, BGLAP, COL1A2, AFP, LPL, ACTA1, TNN13, TPM1) проводилось методом RT-PCR (амплификация продуктов обратной транскрипции).

**Результаты:** В большинстве случаев культура клеток, прилипших к пластику была гетерогенна: наблюдали узкие веретенообразные клетки и большие полигональные. В ряде образцов обнаруживали небольшие колонии (до 100 клеток). В 3 из 43 исследованных образцов ПК наблюдали крупные колонии, численностью более 1000 плотноупакованных, имеющих типичную для фибробластов веретенообразную форму клеток. При анализе преобладающих клеточных типов было выявлено, что большую часть прикрепленных к пластику клеток составляли гемопоэтические клетки (медиана 60,17%). Около трети от всей CD45-положительной популяции составляли CD14-положительные клетки. Остальные негемопоэтические клетки представляли собой фенотипически гетерогенную популяцию. На фоне длительного культивирования и последовательного пассирования фенотип культуры меняется – отмечается элиминация из культуры гемопоэтических клеток и увеличение доли МСК и ЭКП. При инициации культуры значительно изменяется соотношение ГСК- и ЭКП-подобных клеток среди CD34-положительной популяции в пользу ЭКП. МСК-подобные клетки МКПК способны к дифференцировке в адипоциты и остеобласты, что подтверждается специфической окраской и свидетельствует в пользу их функциональной состоятельности. В ряде культур индукция дифференцировки инициировала открепление большей части клеток. Прилипающая фракция первичной монослойной культуры оказывает стимулирующее влияние на колониобразование КОЕ-ГМ, по характеру и силе воздействия близкое стандартному лейкоцитарному фидеру. Преимущественное влияние на их пролиферативную активность оказывают клеточные элементы с маркерами МСК (CD90<sup>+</sup>CD31<sup>-</sup>). Удлинение временных параметров получения и хранения образцов ПК приводят к снижению гемостимулирующей активности. При сравнении экспрессии ряда генов выявлено, что профиль экспрессии МСК костного мозга и клеток МКПК идентичен за исключением тромбopoэтина, экспрессия гена которого не отмечалась в МКПК.

**Заключение:** Пуповинная кровь содержит субпопуляции клеток негемопоэтического происхождения, фенотипически и функционально сходных с МСК костного мозга. Однако их низкая концентрация, а также сниженная репопулирующая активность в стандартных культуральных условиях, ставят под сомнение возможное использование ПК в качестве альтернативного источника МСК.

**Ключевые слова:** пуповинная кровь человека, мезенхимальные стволовые клетки, иммунофенотипирование, культура клеток
